Background—Large multicenter studies validating the prognostic value of coronary computed tomographic angiography (CCTA) and left ventricular ejection fraction (LVEF) are lacking. We sought to confirm the independent and incremental prognostic value of coronary artery disease (CAD) severity measured using 64-slice CCTA over LVEF and clinical variables.

Methods and Results—A large international multicenter registry (CONFIRM Registry) was queried, and CCTA patients with LVEF data on CCTA were screened. Patients with a history of myocardial infarction, coronary revascularization, or cardiac transplantation were excluded. The National Cholesterol Education Program-Adult Treatment Panel III risk was calculated for each patient, and CCTA was evaluated for CAD severity (normal, nonobstructive, non–high-risk, or high-risk CAD) and LVEF <50%. Patients were followed for an end point of all-cause mortality; 27 125 patients underwent CCTA at 12 participating centers, with a total of 14 064 patients meeting the analysis criteria. Follow-up was available for 13 966 (99.3%) patients (mean follow-up of 22.5 months; 95% confidence interval, 22.3 to 22.7 months). All-cause mortality (271 deaths) occurred in 0.65% of patients without coronary atherosclerosis, 1.99% of patients with nonobstructive CAD, 2.90% of patients with non–high-risk CAD, and 4.95% for patients with high-risk CAD. Multivariable analysis confirmed that LVEF <50% (hazard ratio, 2.74; 95% confidence interval, 2.12 to 3.51) and CAD severity (hazard ratio, 1.58; 95% confidence interval, 1.42 to 1.76) were predictors of all-cause mortality, and CAD severity had incremental value over LVEF and clinical variables.

Conclusions—Our results demonstrate that CCTA measures of CAD severity and LVEF have independent prognostic value. Incorporation of CAD severity provides incremental value for predicting all-cause death over routine clinical predictors and LVEF in patients with suspected obstructive CAD. (Circ Cardiovasc Imaging. 2011;4:463-472.)

Key Words: computed tomography ■ coronary angiography ■ prognosis ■ all-cause mortality ■ left ventricular ejection fraction
Prior studies have demonstrated superior operating characteristics for cardiac computed tomographic angiography (CCTA), and CCTA has had increasing acceptance into daily clinical practice for the diagnosis of obstructive coronary artery disease (CAD). Single-center studies suggest that CCTA has prognostic value for both all-cause mortality and major adverse cardiac events. However the validation of CCTA prognosis in large multicenter cohorts is lacking.

Previously, in a single-center study, the severity of CAD and left ventricular ejection fraction (LVEF) have been demonstrated to predict major adverse cardiac events and all-cause mortality. The objective of the present study is to confirm the prognostic and incremental value of CAD severity and LVEF in a large international multicenter cohort of patients undergoing CCTA.

Methods

Centers with prospectively collected CCTA databases (previously published and unpublished data) using at least 64-slice CT were invited to contribute to a larger multicenter observational registry. Qualifying sites contributed baseline demographics, cardiac risk factors, CCTA findings, and outcomes such as all-cause mortality and major adverse cardiac events. Between February 2003 and December 2009, 27,125 consecutive patients underwent CCTA at 12 enrolling centers in 6 countries (Canada, Germany, Italy, Korea, Switzerland, and the United States) and were prospectively entered into an international multicenter Cardiac CT Registry (CONFIRM Registry). Each enrolling center contributed 499 to 4912 patients for analysis. CCTA patients with concomitant CT LVEF assessment were screened for study analysis. Patients with a history of myocardial infarction, coronary revascularization (coronary artery bypass and/or percutaneous coronary intervention), or cardiac transplantation were excluded from analysis. Follow-up procedures were approved by all study centers’ institutional review boards.

Clinical Predictors

A medical history was recorded for all patients. Patients’ pretest probability for obstructive CAD was calculated by using age, sex, and symptoms, and each patient’s risk of future cardiac event was estimated using National Cholesterol Education Program-Adult Treatment Panel (NCEP-ATP) III guidelines.

CCTA Measures: CAD Severity and LVEF

Coronary CT angiography image acquisition and interpretation were performed as per clinical routine at each participating center. All scanners were single- or dual-source 64-slice CT scanners. Coronary diameter stenoses were graded using a 4-point score [normal, mild (<50%), moderate (50% to 69%), or severe (≥70%)]. Patients were categorized as normal, nonobstructive CAD, non-high-risk obstructive (≥50% diameter stenosis) CAD, and high-risk CAD (defined as having a left main stenosis (≥50%), or 3-vessel disease (≥70%), or 2-vessel disease (≥70%) involving the proximal left anterior descending artery). LVEF was calculated using end-diastole and end-systole volumes and LVEF <50% was considered abnormal.

Patient Follow-Up

Patient follow-up for all-cause mortality was performed by each local institution by telephone interview, with validation of reported death through medical records whenever possible and/or a national death registry.

Statistical Analysis

Statistical analyses were performed using SAS (version 9.2, SAS Institute Inc, Cary, NC), and statistical significance was defined as P<0.05. Continuous variables were presented as means and standard deviations, and categorical variables were presented as frequencies with percentages. To compare patient characteristics, the Wilcoxon rank sum test was used to compare continuous variables and the χ² test was used for categorical variables.

The prognostic value of CAD severity and LVEF was assessed for both univariable associations and multivariable associations, with all-cause mortality using Cox proportional hazard models. For the risk-adjusted analysis, the independent prognostic value of LVEF and CAD severity was assessed by controlling for clinical predictors (NCEP/ATP III) and creating adjusted survival curves. Model overfitting was considered, and the proportional hazards assumption was met. The incremental value of LVEF and CAD severity was calculated by defining the clinical predictor model followed by the addition of LVEF and CAD severity.

Receiver-operator characteristic curves were constructed for the models of clinical predictors only, clinical + LVEF, and clinical + LVEF + CAD severity, respectively. The area under the receiver-operator characteristic curves (95% confidence intervals) was compared to evaluate the discrimination ability of LVEF over clinical predictors and CAD severity over clinical + LVEF to predict all-cause mortality using the method proposed by DeLong et al. The improvement of reclassification using CAD severity and LVEF was assessed using a recently published method that estimated the net reclassification improvement (NRI). For calculating the NRI, rescaled individual predicted risks from models with and without LVEF or with and without CAD severity were compared with the 10-year NCEP/ATP III risk by the observed 4-year event rate. This approach separately analyzed the reclassification of persons who had events and those who did not have events. Upward movement/improvement in reclassification occurred when patients with death were appropriately classified into a higher-risk group, and reclassification downward occurred when the test failed to identify a patient with an event. Among patients without death, reclassification upward was considered disadvantageous and reclassification downward was considered advantageous. Improvement in reclassification was estimated by taking the sum of differences in proportions of individuals reclassified upward minus the proportion reclassified downward for patients who had death and the proportion of individuals moving downward minus the proportion moving upward for those who did not have death. The statistical significance of the overall improvement was assessed with an asymptotic test.

A similar analysis was performed using a subgroup of 7015 CCTA patients with absolute LVEF measures to evaluate the incremental value of LVEF as a continuous variable. A secondary analysis was also performed that included patient symptoms (chest pain and dyspnea) in the multivariable analysis.

Results

The CONFIRM registry screened 27,125 CCTA patients at 12 participating centers. Of the 15,168 patients with clinical variables, CAD severity and LVEF assessment (normal versus abnormal LVEF), 1104 patients were excluded for a history of coronary revascularization and/or cardiac transplant. Of the 14,064 patients eligible for analysis, 7015 (50.2%) patients had absolute LVEF measurements; 98 (0.7%) patients were lost to follow-up. The final study population comprised 13,966 (99.3%) patients (mean age, 56.6±13.2 years; 50.9% men), with a median follow-up of 22.5 months (95% CI, 22.3 to 22.7) (Table 1).
All-Cause Mortality
At follow-up, all-cause mortality was observed in 271 patients (1.94%), with an annualized mortality rate for the entire study cohort of 1.06%. The absence of coronary atherosclerosis conferred an excellent prognosis, with only 38 (0.65%) deaths and an annual mortality rate of 0.36%. Patients with nonobstructive CAD had a death rate of 1.99% (n/H11005 89), which equates to an annualized mortality rate of 1.14%.

Death occurred in 90 of the 1818 patients (4.95%) with high-risk CAD compared with 54 (2.90%) of 1861 patients with non–high-risk CAD. The mean LVEF of patients who died was lower than those who survived (54.0±17.7% and 62.0±11.4%, respectively). Of the 1887 patients with abnormal LVEF, 87 (4.61%) died compared with 184 (1.52%) deaths in patients with normal LVEF. Patients with high-risk CAD had an annual death rate of 2.63% compared with 1.41% in patients with non–high-risk CAD.

Cox Models of Risk-Adjusted Outcomes
In univariate analysis, clinical parameters (age, chest pain, dyspnea, cardiac risk factors, body mass index, and NCEP/ATP III) and CT parameters (severity of CAD and abnormal LVEF) were significant predictors for all-cause mortality (Table 2). For the risk-adjusted analysis, the NCEP/ATP III
score was used as a clinical predictor to determine the incremental value of CCTA measures because it combined age, sex, and cardiac factors into a single measure. A multivariable Cox model of CAD severity and abnormal LVEF was tested, and CAD severity and abnormal LVEF remained independent predictors of all-cause mortality after adjusting for clinical characteristics (Figures 1 and 2 and Tables 3 and 4). Patient symptoms were included in a secondary analysis and showed that chest pain appeared to be protective (hazard ratio, 0.65; [0.51 to 0.83]) and that dyspnea did not have independent prognostic value (Table 5). The addition of symptoms to the Cox models did not alter the prognostic value of CCTA.

Receiver-operator characteristic curves were created for clinical predictors and the models with each CCTA measure, and the area under the curve was compared to assess the discrimination ability of each additional measure (Figure 3). The addition of each variable resulted in a significant improvement in the area under the curve ($P<0.001$).

Absolute LVEF was available for 7015 (50.2%) patients, and a subanalysis was performed using LVEF as a continuous variable. These results also confirmed the independent and incremental prognostic value of LVEF (Table 5).

### Incremental Prognostic Value of CAD Severity and LVEF

The incremental prognostic value of abnormal LVEF and CAD severity over clinical predictors was evaluated. The patient classification was significantly improved when LVEF was added to a model containing clinical variables only (NRI, 22.5%; $P<0.001$). A total of 50 (18.5%) patients who had an event were appropriately reclassified upward, and a total of 35 (12.9%) patients who had an event were reclassified downward. Similar calculations for patients who did not have an event revealed a total of 3248 (23.7%) patients who were correctly reclassified downward and a total of 917 (6.7%) patients who were reclassified upward. Also, when CAD severity was added to a model containing clinical variables and LVEF, a total of 53

Homogeneity of Results

The homogeneity of the results was evaluated across different sites. Overall, there is no significant heterogeneity identified. For the risk-adjusted analysis, CAD severity and abnormal LVEF remained independent predictors of all-cause mortality after adjusting for clinical characteristics. The direction of hazard ratios for CAD severity and abnormal LVEF was consistent across different sites.

Discussion

In the present analysis of the international multicenter CONFIRM Registry, we observed an additive prognostic value of CCTA-measured LVEF and CAD severity for the prediction of all-cause mortality. Both CAD severity and abnormal LVEF had incremental prognostic value over baseline clinical variables alone, and the CAD severity was incremental to LVEF+clinical variables.

Prognostic Value of CCTA

Several single-center studies have examined the prognostic value of CCTA and the incremental value of LVEF above CAD severity. Our results expand on previous literature by confirming that measures of CCTA (CAD severity and abnormal LVEF) have prognostic value in a large international multicenter registry. The variety of sites included in the analysis ensures that these measures are clinically useful across different ethnicities and different institutions with potentially different CCTA reading thresholds. Similarly, the different centers used different CT platforms and postprocessing software, suggesting that assessments of LVEF and CAD severity were independent of vendor.

With the increasing use of prospective ECG-triggered image acquisition to minimize patient radiation exposure, LVEF may not be routinely available with all CCTA.
However, based on our results, the assessment of LVEF should be considered if the end-systolic and end-diastolic datasets are available.

Compared with existing modalities (echocardiography, radionuclide angiography, and cardiac MRI) commonly used to assess LVEF, the temporal resolution of contemporary multislice CT scanners is suboptimal. This limitation may result in the underestimation of end-systolic LV volumes and potentially the underestimation of LVEF. However, recent comparisons of LVEF by CCTA to MRI have shown tight agreement, and our results suggest that the measurement of LVEF with CT remains of high clinical value. The authors recognize that LVEF assessment is commonly available before CCTA. To ensure that CAD severity had incremental prognostic value over LVEF, the sequence of analysis was modified to reflect this scenario. This new model demonstrated that LVEF had incremental value over clinical predictors, and the CAD severity was incremental to LVEF and clinical variables combined with an NRI of 17.8% ($P<0.001$).

There is mounting enthusiasm for characterization of coronary atherosclerosis and its potential prognostic value over CAD severity and LVEF. Because the coronary calcium scores and plaque characterization were not uniformly available for our study cohort, the incremental values of these measures were not examined.

Prognostic Value of Symptoms

Because patient symptoms may have prognostic value, chest pain and dyspnea were individually evaluated in the multivariable analysis. Dyspnea did not have incremental value over NCEP/ATPIII risk + chest pain. Conversely, chest pain appeared to be protective and was associated with improved survival. Though this finding appears counterintuitive, patient symptoms may have biased patient treatment (medical therapy, revascularization, and downstream investigations). Importantly, inclusion of chest pain in the multivariable analysis did not change the prognostic power of CCTA.

Limitations

All-cause mortality was used as the primary outcome measure, and the specific causes of death for each patient were not available. Although a previous study demonstrated that 41% of all deaths were related to cardiac causes, the proportion of deaths that may have been attributable to cardiac or cardiovascular events is unknown. Because the NCEP/ATPIII is traditionally used to predict future cardiovascular events and not all-cause mortality, the authors recognize the potential limitations of NCEP/ATPIII for predicting all-cause mortality. Such limitations could result in overestimating the prognostic value of CCTA. Similarly, the ability of CT measures to predict cardiac and cardiovascular events (myocardial infarction and cardiac death) in the COMFIRM Registry cannot be verified. Body mass index, a potential measure with prognostic value, was not reported by all centers and therefore could not be used in the multivariable analysis. Such exclusion could result in the overestimation of CCTA’s prognostic value.

The availability of fasting lipid profiles was not uniformly available at all centers. For patients with available fasting lipid profile results, the NCEP was calculated. Because some patients were already being treated with a statin, the fasting lipid profile may not represent their true risk. Because the NCEP/ATP III model was created in a statin-naive population, patients receiving statin therapy were presumed to have dyslipidemia and were considered to have elevated total cholesterol values and normal HDL. As well, changes in medical therapy as a result of CCTA results were not documented. However, aggressive risk factor modification may reduce cardiovascular events, biasing the results against CCTA.

Not all centers collected information regarding early revascularization. The authors also recognize that patients...
diagnosed with obstructive CAD are more likely to undergo revascularization, which may improve patient survival. This could lead to lower mortality rates in the cohort, resulting in the underestimation of the true prognostic value of CCTA.

Not all participating centers reported absolute percent LVEF; thus LVEF could not be analyzed as a continuous variable for the entire cohort. Because data regarding “abnormal LVEF” (<50%) was available at most centers, LVEF was analyzed as a categorical variable. However, a subanalysis of 7015 patients with absolute LVEF measurements confirmed the findings in the larger cohort.

Conclusions
Our results demonstrate that CCTA measures of CAD severity and LVEF have independent prognostic value. CAD severity has incremental value over LVEF + clinical variables for predicting all-cause death.

CLINICAL PERSPECTIVE

The prognostic value of cardiac computed tomographic angiography has been demonstrated in single center studies; however, large multicenter studies validating the prognostic value of CCTA and LVEF are lacking. Using a large international multicenter registry (CONFIRM Registry) of 27,125 patients, we sought to confirm the independent and incremental prognostic value of coronary artery disease (CAD) severity measured using 64-slice CT over left ventricular ejection fraction (LVEF) and clinical variables. Multivariable analysis of 14,064 patients, confirmed that LVEF <50% (hazard ratio, 2.74 [2.12 to 3.51]) and CAD severity (hazard ratio, 1.58; 95% confidence interval, 1.42 to 1.76) were predictors of all-cause mortality and CAD severity had incremental value over LVEF and clinical variables. Our results demonstrate that CCTA measures of CAD severity and LVEF have independent prognostic value. Incorporation of CAD severity provides incremental value for predicting all-cause death over routine clinical predictors and LVEF in patients with suspected obstructive CAD.
