Abstract

Background—LGE CMR is a powerful method for characterizing MI, but the requisite gadolinium infusion is estimated to be contraindicated in nearly 20% of MI patients due to end-stage chronic kidney disease. The purpose of this study is to investigate whether T\textsubscript{1} Cardiovascular-Magnetic-Resonance Imaging (CMR) obtained without contrast agents at 3T could be an alternative to Late-Gadolinium-Enhanced (LGE) CMR for characterizing chronic myocardial infarctions (MIs) using a canine model of MI.

Methods and Results—Canines (n=29) underwent CMR at 7 days (acute, AMI) and 4 months (chronic, CMI) post-MI. Infarct location, size and transmurality measured using native T\textsubscript{1} maps and LGE images at 1.5T and 3T were compared. Resolution of edema between AMI and CMI was examined with T\textsubscript{2} maps. T\textsubscript{1} maps overestimated infarct size and transmurality relative to LGE images in AMI (p=0.016 and p=0.007, respectively), which was not observed in CMI (p=0.49 and p=0.81, respectively), at 3T. T\textsubscript{1} maps underestimated infarct size and transmurality relative to LGE images in AMI and CMI (p<0.001), at 1.5T. Relative to the remote territories, T\textsubscript{1} of the infarcted myocardium was increased in CMI and AMI (p<0.05); and T\textsubscript{2} of the infarcted myocardium was increased in AMI (p<0.001), but not in CMI (p >0.20) at both field strengths. Histology showed extensive replacement fibrosis within the CMI territories. CMI detection sensitivity and specificity of T\textsubscript{1} CMR at 3T were 95% and 97%, respectively.

Conclusions—Native T\textsubscript{1} maps at 3T can determine the location, size and transmurality of CMI with high diagnostic accuracy. Patient studies are necessary for clinical translation.

Key Words: myocardial infarction, viability imaging, fibrosis, T\textsubscript{1} mapping
Prognostic outcome in patients with myocardial infarction (MI) is significantly determined by the location, size and transmurality of the MI\textsuperscript{1-5}. Over the past decade, Late Gadolinium Enhancement (LGE) Cardiac Magnetic Resonance Imaging (CMR) has evolved into a robust non-invasive imaging technique for detecting acute MIs (AMI) and chronic MIs (CMI) with excellent diagnostic accuracy and prognostic significance\textsuperscript{6-8}. However, accurate infarct sizing using LGE imaging is limited by the gadolinium kinetics\textsuperscript{9-11}, effective nulling of the remote myocardium\textsuperscript{12}, and its qualitative nature. Contrast-enhanced $T_1$ mapping has been proposed as a potential alternative as it is quantitative in nature, and does not require nulling of the remote myocardium\textsuperscript{13,14}. Nevertheless, like LGE imaging, the $T_1$ value of infarcted myocardium in contrast-enhanced $T_1$ mapping depends on the gadolinium kinetics\textsuperscript{15}. Moreover, once contrast-enhanced imaging is deemed necessary for assessment of myocardial viability, all other imaging sequences are typically required to be prescribed ahead of LGE imaging, which could impose practical limitations on the execution of the imaging exam, especially when rapid assessment of viability is all that may be necessary. Finally, perhaps most importantly, contrast-enhanced imaging requires administration of a gadolinium chelate, which is contraindicated in patients with chronic end-stage kidney disease\textsuperscript{16}, which is a rising epidemic\textsuperscript{17}. In fact, according to the United States Renal Data System, the fraction of patient with cardiovascular disease, who have chronic kidney disease is >40%. Recent studies have shown that approximately 20% of AMI (STEMI and NSTEMI) patients suffer from late stage chronic kidney disease (GFR <45 mL/min/1.73m$^3$), in whom LGE is expected to be contraindicated\textsuperscript{18,19}.

By definition, native $T_1$ mapping does not require exogenous contrast media. Hence in addition to the patients with renal insufficiency, the technique can be safely used in significant fraction of patients for whom LGE imaging or contrast-enhanced $T_1$ mapping is warranted but
are contraindicated for gadolinium. Recent studies have shown that native T₁ mapping can reliably detect AMI at both 1.5T and 3T¹³, ¹⁰⁻²². In contrast, the diagnostic performance of native T₁ mapping to detect CMI has been shown to be poor at 1.5T¹³. Preliminary studies in non-ischemic cardiac pathologies in animals and humans have noted intrinsic T₁ dependence on myocardial collagen content²³. Recent studies have demonstrated the tremendous potential of native T₁ mapping at 3T to reliably detect and quantify diffuse myocardial fibrosis in non-ischemic settings, such as aortic stenosis²⁴, hypertrophic cardiomyopathy²⁵,²⁶ and dilated cardiomyopathy²⁵,²⁶.

We hypothesized that magnetic field dependent T₁ elongations permit native T₁ mapping to reliably detect and quantify replacement myocardial fibrosis associated with CMI at 3T. To test our hypothesis, we rigorously studied the native T₁ characteristics against LGE features of myocardial images acquired at 1.5T and 3T using canine models of AMI and CMI.

Methods

Animal Model

Canines (n = 33; 20-25 kg body weight) were studied according to the protocols approved by Institutional Animal Care and Use Committees. Myocardial infarction was created by ligating the left anterior descending (LAD) artery for 3 hours followed by reperfusion. Animals were allowed to recover for 7 days before the Cardiac Magnetic Resonance (CMR) studies.

Cardiac Magnetic Resonance Studies

Four canines died during the first few hours of reperfusion despite resuscitation efforts. The remaining 29 canines underwent CMR studies at 7 days (acute) and 4 months (chronic)
following reperfusion. Nineteen of the 29 canines were scanned on a 3T clinical MRI system (MAGNETOM Verio®, Siemens Healthcare, Erlangen, Germany), while the remaining ten canines were scanned on a 1.5T clinical MRI system (MAGNETOM Espree®, Siemens Healthcare, Erlangen, Germany). ECG-triggered breath-held cine-SSFP, native T₁-weighted and T₂-weighted images of contiguous slices covering the entire LV were acquired along the short-axis views at both 3T and 1.5T. All imaging studies were completed with the acquisition of Late Gadolinium Enhancement (LGE) images 8-10 minutes following intravenous administration of 0.2 mmol/kg gadopentate dimeglumine (Magnevist, Bayer Healthcare Pharmaceuticals Inc., Wayne, NJ). Imaging sequences and measurement parameters used to acquire the various images are summarized in Table 1. To minimize surface coil bias, pre-scan normalization was applied for each scan.

**Histopathology**

All animals were euthanized following the 4-month CMR study and their hearts were excised. Ex-vivo triphenyl tetrazolium chloride (TTC) staining and Elastin Masson’s Trichrome (EMT) staining were performed.

**Image Analyses**

T₁ and T₂ maps were constructed from the native T₁-weighted and T₂-weighted images, respectively. All image analyses were performed on cvi42 image analysis software (Circle Cardiovascular Imaging Inc., Calgary, Canada). Remote (viable) myocardium was identified on LGE images as the region showing no hyperintensity and a reference ROI was drawn in it. Infarcted myocardium was identified on the LGE image as the region with mean signal intensity
(SI) >5 standard deviations (SDs) than that of reference ROI\textsuperscript{27-29}. Hypointense cores of microvascular obstruction that were not detected as infarcted myocardium on LGE images by the thresholding criterion were manually included in the final analysis for infarct size and transmurality. The reference ROI drawn on LGE image was copied on to the corresponding T\textsubscript{1} map. Infarcted myocardium was then identified on the T\textsubscript{1} map using the mean+5SD criterion. To account for the dependence of MOLLI T\textsubscript{1} values on heart rate, the T\textsubscript{1} values were corrected and the threshold was further adjusted as previously described\textsuperscript{13}. Hypointense cores of acute hemorrhage or chronic iron deposition\textsuperscript{30,31} that were not detected as infarcted myocardium on T\textsubscript{1} maps by the thresholding criterion were manually included in the final analysis for infarct size and transmurality.

Infarct sizes from both LGE images and T\textsubscript{1} maps were measured as the percentage of total left-ventricular (LV) volume, as well as on the basis of standard American Heart Association (AHA) 17-segment model. Measurements from the 17\textsuperscript{th} segment were excluded from the final analysis to discount the partial volume effects at the apical cap. Infarct transmurality was determined as the percentage extent of the infarct along 100 equally spaced chords on each slice. Mean transmurality was obtained by averaging the infarct transmurality across all the chords that have at least 1\% scar extent.

T\textsubscript{1} and T\textsubscript{2} values of the remote and infarcted myocardium (as identified on LGE images using mean+5SD criterion) were measured from T\textsubscript{1} and T\textsubscript{2} maps respectively. Hypointense cores within infarcted myocardium were excluded from this analysis to eliminate the confounding effects of acute hemorrhage or chronic iron deposition on acute myocardial edema or chronic replacement fibrosis.
**Statistical Analyses**

Statistical analyses were performed using IBM SPSS Statistics (version 21.0, IBM Corporation, Armonk, New York). Normality of the data was tested using the Shapiro-Wilk test and quantile-quantile plots. Depending on the normality of the data, percentage infarct size and mean transmurality measured over the entire LV were compared between LGE images and T1 maps using either paired t-test or Wilcoxon signed-rank test. Additionally, mixed-model ANOVA was used to compare percentage segmental infarct size measured from the two techniques. Bland-Altman analysis was performed to estimate the agreement between the two techniques. Simple linear regression was performed to estimate the correlation between the two techniques with respect to infarct size and transmurality measurements. Measurements from the native T1 maps and LGE images were chosen as the dependent and explanatory variables respectively. The slope and the intercept of the best fit line were tested to be equal to 1 and 0 respectively. Using LGE images as the gold standard, sensitivity and specificity of native T1 maps to detect infarcted myocardium at the segmental level were measured. Receiver operating characteristic (ROC) analysis was performed to measure area under the curve (AUC). The predictor variable used to generate the ROC curves was the infarct size measured on a segmental basis from the T1 maps.

T1 and T2 values of the remote and infarcted myocardium were compared using mixed-model ANOVA. Similarly, percentage change in the LGE-SI of infarcted myocardium relative to remote myocardium was compared to the percentage change in T1. Statistical significance was set at p<0.05 for all analyses.
Results

Detection of Acute Myocardial Infarction at 3T

All canines sustained MIs as verified by the presence of gadolinium hyperenhancement on LGE images acquired at 7 days post-reperfusion. Representative LGE images and T₁ maps acquired at 7 days post-MI from a canine scanned at 3T are shown in Figure 1. Bulls-eye plots depicting the infarct extent on 17-segment model and transmurality are also shown for both LGE images and T₁ maps in Figure 1. Infarct location and spatial extent were visually well correlated between LGE images and T₁ maps. In AMI at 3T, T₁ maps modestly overestimated infarct size (13.3±8.4% vs. 11.6±6.8%, p=0.007) and transmurality (64±19% vs. 56±17%, p=0.007) relative to LGE images. Mean segmental infarct size measured using T₁ maps was also greater than that measured using LGE images (p=0.016). Bland-Altman analysis showed good agreement between LGE images and T₁ maps for measuring infarct size (Bias = 2.22±2.34%; Figure 2A) and transmurality (Bias = 7.07±10.25%; Figure 2B). Strong correlations were observed between LGE images and T₁ maps for measuring infarct size ($R^2=0.94$; Slope=1.20, p=0.011; Intercept=0.01, p=0.98; Figure 2C) and transmurality ($R^2=0.72$; Slope=0.93, p=0.62; Intercept=11.14; p=0.20; Figure 2D). At 3T, T₁ maps detected AMI in 149 of 158 segments that were positive for infarction on LGE images (94% sensitivity; 95% confidence interval (CI): 90-98). T₁ maps were negative for AMI in 138 of 146 segments (94% specificity; 95% CI: 91-98). ROC analysis showed that the area under the curve was 0.96 (Figure 2E).

Detection of Chronic Myocardial Infarction at 3T

Representative LGE images and T₁ maps, along with the bulls-eye plots for infarct extent and transmurality, acquired from a canine scanned at 3T at 4 months post MI are shown in Figure 3.
Infarct locations and its spatial extent were visually identical on LGE images and T₁ maps in CMI. There was no significant difference between the LGE images and T₁ maps for measuring infarct size (5.6±3.7% vs. 5.5±3.7%; p=0.61) and transmurality (44±15% vs. 46±15%; p=0.81). Mean segmental infarct size, measured using T₁ maps, was not different compared to that measured using LGE images (p=0.49). Bland-Altman analysis showed excellent agreement between LGE images and T₁ maps for measuring infarct size (Bias = -0.08±0.68%; Figure 4A) and transmurality (Bias = 0.45±8.14%; Figure 4B). Excellent correlations were observed between LGE images and T₁ maps for measuring infarct size (R²=0.97; Slope=0.98, p=0.68; Intercept=0.02, p=0.94; Figure 4C) and transmurality (R²=0.75; Slope=0.84, p=0.18; Intercept=8.11, p=0.18; Figure 4D). At 3T, T₁ maps detected CMI in 135 of 142 segments that were positive for infarction on LGE images (95% sensitivity; 95% CI: 92-99). T₁ maps were negative for CMI in 158 of 162 segments (97% specificity; 95% CI: 95-100). ROC analysis showed that the area under the curve was 0.99 (Figure 4E).

**Detecting Acute Myocardial Infarction at 1.5T**

Representative LGE images and T₁ maps, along with bulls-eye plots (obtained using the mean+5SD criterion), acquired from a canine scanned at 1.5T at 7 days post MI are shown in Supplementary Figure 1. Infarct location was visually well correlated between LGE images and T₁ maps at 1.5T. However, using the mean+5SD criterion at 1.5T, T₁ maps significantly underestimated the infarct size (9.4±5.6% vs. 15.5±9.4%, respectively, p<0.001) and transmurality (59±5% vs. 76±6%, respectively, p<0.001) in AMI relative to LGE images. Segmental comparison of infarct sizes also showed significant underestimation by T₁ maps compared to LGE images (p<0.001). Bland-Altman analysis showed moderate agreement...
between LGE images and T₁ maps for measuring infarct size (Bias = -8.07±4.6%; Figure 5A) and transmurality (Bias = -17.61 ±3.27%; Figure 5B) measured using the mean+5SD criterion. However, strong correlations were observed between LGE images and T₁ maps for measuring acute infarct size (R²=0.86; Slope=0.57, p<0.001; Intercept = –1.40, p=0.36; Figure 5C) and transmurality (R²=0.77; Slope=0.71, p=0.06; Intercept=4.63, p=0.66; Figure 5D). At 1.5T, T₁ maps were positive for AMI in 92 of 110 segments (84% sensitivity; 95% CI: 77-91), and negative for AMI in 37 of 50 segments (74% specificity; 95% CI: 62-86). ROC analysis showed that the area under the curve was 0.86 (Figure 5E). Using the previously reported mean+3SD criterion for detecting AMI on T₁ maps at 1.5T, infarct size (16.4±8.2%) and transmurality (81±9%) measured using T₁ maps were not significantly different from those measured using the mean+5SD criterion on LGE images (p=0.28 for infarct size and p=0.18 for transmurality).

Detecting Chronic Myocardial Infarction at 1.5T

Representative LGE images and T₁ maps, along with bulls-eye plots (obtained using the mean+5SD criterion), acquired from a canine scanned at 1.5T at 4 months post-MI are shown in Supplementary Figure 2. Mean infarct size (2.1±1.2% vs. 4.8±1.8%, p<0.001) and transmurality (47±7% vs. 66±9%, p<0.001) measured on T₁ maps using the mean+5SD criterion in CMI were significantly lower than those measured on LGE images. Segmental comparison of infarct sizes in CMI showed significant underestimation by T₁ maps compared to LGE images (p<0.001). Bland-Altman analysis showed poor agreement between LGE images and T₁ maps for measuring infarct size (Bias = -2.74±1.31%; Figure 6A) and transmurality (Bias = -19.67±6.70%; Figure 6B). Moderate correlations were observed between LGE images and T₁ maps for measuring infarct size (R²=0.44; Slope=0.43, p=0.004; Intercept= – 0.03, p=0.97; Figure 6C) and
transmurality ($R^2=0.51$; Slope=0.61, p=0.10; Intercept=6.60, p=0.65; Figure 6D). At 1.5T, $T_1$ maps were positive for CMI in 52 of 90 segments (58% sensitivity; 95% CI: 48-68), and negative for CMI in 55 of 70 segments (78% specificity; 95% CI: 69-88). ROC analysis showed that area under the curve was 0.79 (Figure 6E). Using the less stringent mean+3SD criterion for detecting CMI on $T_1$ maps at 1.5T, $T_1$ maps still significantly underestimated the infarct size and transmurality relative to those measured using mean+5SD criterion on LGE images (infarct size from $T_1$ map: 3.4±1.6%, p<0.001; transmurality from $T_1$ map: 52±20%, p<0.001).

$T_1$, $T_2$ and LGE Characteristics of Infarcted Myocardium at 3T and 1.5T in Acute and Chronic Infarctions

Table 2 summarizes the $T_1$, $T_2$ and LGE-SI characteristics of infarcted and remote myocardium at 3T and 1.5T at 7 days and 4 months post-MI. Representative LGE images, $T_1$ maps and $T_2$ maps acquired from four different canines at 3T and 1.5T during the acute and chronic phases of MI are shown in Figure 7.

Compared to remote myocardium, mean $T_1$ and $T_2$ of the infarcted myocardium were increased by 329±119ms and 18±6ms respectively in AMI at 3T (p<0.001 for both cases). In terms of infarcted to remote myocardium contrast, percentage change in LGE-SI was nearly 28-fold higher than percentage change in $T_1$ (p<0.001). However, the coefficient of variation (CV) of the percentage change in LGE-SI was two-fold higher than percentage change in $T_1$ (0.66 vs. 0.30) indicating a greater variability in LGE versus $T_1$ image contrast.

In CMI, significant $T_1$ increase was still visually evident within infarcted myocardium at 3T, while edema within the infarcted myocardium, typically visualized via $T_2$ images, appeared to have resolved. Mean $T_1$ of infarcted myocardium in CMI at 3T was increased by 239±104ms.
with respect to remote myocardium (p<0.001), while mean difference in T2 values of infarcted and remote myocardium in CMI at 3T was not statistically significant (2±3ms; p=0.19). Mean T1 of the infarcted myocardium in CMI was significantly lower than that in AMI (p<0.001). However, no significant difference was observed between mean T1 values of remote myocardium measured during the acute and chronic phases (p=0.21). Consistent with the acute studies, percentage change in LGE-SI was nearly 40-fold higher than percentage change in T1 (p<0.001). However, the CV of percentage change in LGE-SI was 1.5-fold higher (0.65) compared to percentage change in T1 (0.42), again indicating a higher degree of variability in LGE versus T1 image contrast.

In AMIs at 1.5T, significant T2 increase was visually evident within infarcted myocardium, while moderate T1 increase was visible in infarcted myocardium. Mean T1 of infarcted myocardium at 1.5T in AMI was 184±77ms higher than that of remote myocardium (p<0.001), while mean T2 of infarcted myocardium was 20±7ms higher than that of remote myocardium (p<0.001). Percentage change in the LGE-SI was nearly 26-fold higher than percentage change in T1 at 1.5T (p<0.001). Compared to 1.5T, infarcted to remote myocardium T1 contrast in AMI was nearly 2-fold higher at 3T.

After 4 months post-MI, neither T1 nor T2 increase was visually evident within infarcted myocardium at 1.5T. Mean T1 value of infarcted myocardium at 1.5T in CMI was mildly higher by 89±38ms than that of remote myocardium (p=0.037). Mean difference in T2 values of infarcted and remote myocardium was not statistically different from 0 (2±5ms; p=0.55). Mean T1 of the infarcted myocardium in CMI was significantly lower than that in AMI (p<0.001). No significant difference was observed between the mean T1 values of the remote myocardium during the acute and chronic period of MI (p=0.23). Percentage change in the LGE-SI was 34-
fold higher than percentage change in $T_1$ at 1.5T ($p<0.001$). Compared to 1.5T, infarcted to remote myocardium $T_1$ contrast in CMI was nearly 50% higher at 3T.

**Histopathological Validation of Replacement Fibrosis in CMI**

Figure 8 shows representative LGE images and $T_1$ maps acquired at 3T from three different canines at 4 months post-reperfusion along with slice-matched ex-vivo TTC and EMT staining images. Both LGE images and $T_1$ maps agreed well with ex-vivo TTC images in terms of the spatial location of the infarction. EMT staining showed extensive replacement fibrosis within infarcted myocardium, which validated that $T_1$ hyperintensity in the CMI predominantly arose from fibrosis. Similar evidence was observed in the other animals.

**Discussion**

Characterizing CMIs using CMR has immense clinical importance for predicting long-term LV function\(^3\), assessing the efficacy of therapeutic regeneration\(^{32,33}\) and risk stratifying patients for cardiac defibrillator implantation\(^34\). However, the utility of LGE imaging for this purpose is partly limited by the contra-indication of gadolinium infusion in nearly 20% of the patients with AMI with chronic end-stage kidney disease\(^{17-19}\). Non-contrast approaches for viability imaging can, therefore, be of significant value for the clinical and therapeutic management of patients with MI.

Our study confirms the hypothesis that native $T_1$ mapping at 3T can reliably characterize CMIs with high specificity and sensitivity. Using a canine model of MIIs and threshold-based detection of infarcted myocardium, we have demonstrated that native $T_1$ maps at 3T can accurately determine location, size and transmurality of CMI just as well as LGE CMR. We also
found that using the same threshold-based criterion on native T₁ maps at 1.5T tended to
significantly underestimate infarct size and transmurality obtained from LGE images in both
AMI and CMI. We also tested whether using the previously tested, less stringent, mean+3SD
criterion¹³ significantly improves the diagnostic performance of T₁ mapping at 1.5T. Consistent
with the previously reported observations, our results indicated that T₁ maps at 1.5T can reliably
determine infarct size using the mean+3SD criterion in AMI¹³, but significantly underestimates
infarct size at 1.5T in the CMI despite the less stringent criteria. The ability to reliably detect
infarcted myocardium at 3T compared to 1.5T is further explained by our findings that infarcted
to remote myocardium T₁ contrast is 2-fold higher at 3T relative to 1.5T in AMI, and 1.5-fold
higher in CMI. Our results suggested that native T₁ mapping at 3T can be a reliable alternative to
LGE for characterizing CMI with the potential for clinical translation. In addition, our results are
consistent with previously reported observations that myocardial edema, as detected using T₂-
based imaging, resolves in the chronic phase of infarction³⁵, ³⁶, and T₂-based imaging in
conjunction with LGE imaging can be used to differentiate between AMIs and CMIs³⁷. Hence,
together with T₂ and T₁ maps it may be possible to reliably discriminate CMI in much the same
way T₂ imaging is used for discriminating CMI when LGE is available.

LGE imaging and contrast-enhanced T₁ mapping are primarily limited by the association
of gadolinium use to nephrogenic systemic fibrosis in patients with late-stage chronic kidney
disease³⁸, ³⁹. Further, as observed from the high CV in the LGE contrast in our study, gadolinium
kinetics in infarcted and remote myocardium lead to dynamic changes in LGE-SI values and
contrast-enhanced T₁ values which may be irreproducible across different imaging sessions.
These limitations may be overcome by the application of contrast-free techniques for assessing
myocardial infarctions. Recently, T₁ρ imaging was proposed as a potential contrast-free CMR
technique for detecting AMI\textsuperscript{40} and CMI\textsuperscript{41}. However, this technique is limited by its high specific absorption rate (SAR), which can further limit the contrast between infarcted and remote myocardium. Native T\textsubscript{1} mapping overcomes many of the limitations faced by other techniques and opens the door to unique opportunities. First, it enables infarct characterization in patients with poor renal function, and is not SAR-limited. Second, it can improve the work flow demands during imaging exams: (a) allows for infarct characterization typically performed with LGE to be executed in any order within the imaging session, (b) eliminates the need to determine the inversion time, which continually changes as a function of the wash-out kinetics of the gadolinium-based contrast media, and (c) removes the waiting period between contrast administration and LGE acquisitions. Third, since pixel intensities of T\textsubscript{1} maps provide intrinsic T\textsubscript{1} values, it makes the approach inherently quantitative, which permits reliable serial examinations of infarct healing and remodeling, especially when prescribed with a T\textsubscript{1} mapping approach that is less sensitive to heart rate variations\textsuperscript{20}. Finally, it can render significant cost savings since contrast infusions and venous cannulations would become unnecessary and the length of the imaging exam may be reduced.

Previous studies have reported that myocardial edema associated with AMI can be accurately detected and sized using T\textsubscript{1}-weighted imaging\textsuperscript{42} and native T\textsubscript{1} maps at both 1.5T and 3T\textsuperscript{13, 20-22}. Consistently, our study showed that T\textsubscript{1} elevation in AMI is accompanied by T\textsubscript{2} elevation, indicating that the ability of T\textsubscript{1} mapping to reliably detect AMI predominantly arose from increased free water content in infarcted myocardium\textsuperscript{21, 37}. Although the clinical value of native T\textsubscript{1} maps for detecting AMI has been well studied, its potential for assessing CMI has not been fully explored to date. Messroghli et al\textsuperscript{13} and Bauner et al\textsuperscript{14} have shown that, at 1.5T, CMIs are associated with significant increase in native T\textsubscript{1}. However, the diagnostic performance of
native $T_1$ maps at 1.5T to detect CMI has been reported to be poor. Recently, Dall’Armellina and colleagues have reported preliminary case studies at 3T in which $T_1$ hyperenhancement could be observed even in CMI without any concomitant $T_2$ increase\textsuperscript{43}. However, the nature of such $T_1$ hyperenhancement was not fully elucidated. This study showed that that the extensive replacement fibrosis associated with CMI might be responsible for the observed $T_1$ elevations in chronic phase of MI. The reversion of $T_2$ values of infarcted myocardium to baseline levels, which indicates complete resolution of edema\textsuperscript{37}, additionally support the notion that the apparent $T_1$ elevations in CMI may be predominantly due to fibrosis. This is consistent with previous reports showing significant $T_1$ elevations associated with diffuse myocardial fibrosis in non-ischemic cardiomyopathies such as aortic stenosis\textsuperscript{24}, hypertrophic cardiomyopathy\textsuperscript{25,26} and idiopathic dilated cardiomyopathy\textsuperscript{25,26}.

Our study showed that one of the primary reasons that CMIs are more reliably characterized at 3T is due to the biophysical differences in $T_1$ relaxation of remote myocardium and infarcted myocardium at 3T and 1.5T. We found that, as the field strength is increased from 1.5T to 3T, the $T_1$ values of the non-infarcted (remote) myocardium and the infarcted (fibrotic) myocardium are increased by ~29% and ~40% (Table 2), respectively. This is consistent with previous studies, which have rigorously shown that $T_1$ of a given tissue can increase between ~10% to ~70% at 3T compared to 1.5T, and that the extent of the increase is dependent on the type of tissue\textsuperscript{44}. Although the mechanistic underpinnings of native $T_1$ elongation in CMIs are not entirely clear, there are a few possible explanations. One potential mechanism is that the apparent diffusion coefficient in CMIs is higher than that of remote myocardium\textsuperscript{45,46}, which implies greater diffusivity of water molecules, lower viscosity, lower correlation times of molecular motion and hence longer $T_1$ values\textsuperscript{47}. In addition, another possibility is the potential
bias in $T_1$ values measured using MOLLI sequences with SSFP readouts which may be subject to magnetization transfer (MT) effects. Robson et al have shown that MT effects can lead to $T_1$ underestimation by MOLLI. Scholz et al and Weber et al have shown that the MT effects are reduced in AMIs and CMIs, which could potentially lead to longer apparent $T_1$ values within infarcted myocardium. Nevertheless, further studies are necessary to fully elucidate the mechanisms and their relative contributions to the underlying $T_1$ elongations observed in CMIs.

Our study showed that LGE images have a nearly 30-fold higher infarcted to remote myocardium contrast relative to the proposed native $T_1$ maps at 3T. While the high image contrast of infarcted myocardium in LGE images is attributable to the use gadolinium-based contrast agents, the imposed nulling of remote myocardium by inversion-recovery preparation is another significant contributor to the observed contrast. In this context, it should be noted that as in LGE imaging, inversion-recovery preparation may also be introduced to significantly improve image contrast between infarcted and remote myocardium in native $T_1$-weighted techniques as well. Based on the $T_1$ values of remote myocardium (1250 ms) and CMIs (1490 ms) at 3T, an inversion-recovery preparation that nulls remote myocardium gives a 12% equilibrium magnetization available for readout from infarcted myocardium. Similarly, assuming that the contrast-enhanced $T_1$ values (10 minutes post-gadolinium injection) of remote and infarcted myocardium at 3T are 400 ms and 230 ms respectively, an inversion-recovery sequence that nulls remote myocardium (such as conventional LGE imaging) gives a 40% equilibrium magnetization available for readout from infarcted myocardium. This suggests that, if employed, inversion-recovery preparation can potentially increase the image contrast between infarcted and remote myocardium by 900% compared to the current levels. Experimental studies are necessary to confirm these theoretical estimations. Nevertheless, while this is expected to improve the
visualization of CMI, the current T₁ mapping approach evaluated here still provides excellent diagnostic accuracy.

Together with previous studies, our study has shown that native T₁ mapping has great potential for widespread clinical applicability in the setting CMI. While a few studies have assessed the prognostic significance of T₁ hyperenhancement in AMI²¹,²², future studies that elucidate the relationship of T₁ hyperenhancement in the CMI to long-term LV function, collagen metabolism and extracellular matrix remodeling are necessary.

Study Limitations

First, the sample size used in this study is relatively small, but comparable to those used in previous studies in patients with MIs¹³,¹⁴,²¹,²². Second, this study relied on identifying the remote territory on the basis of LGE. Additional studies are necessary to examine whether remote territories can be reliably identified solely on the basis of native T₁ maps. Third, we did not evaluate the proposed approach in the clinical setting. Hence, additional studies are required to determine the diagnostic performance of native T₁ maps in patients with CMI. Third, we limited our analysis to the mean±5SD threshold as this criterion has been shown to be robust for delineating infarcted myocardium in LGE imaging²⁷-²⁹. Nevertheless, a comprehensive study comparing the different thresholding criteria to ex-vivo histology-based infarct sizing may be necessary for further validation. However, such a study needs to take into account potential changes in T₁ following animal sacrifice and registration between CMR images and ex-vivo standard. Finally, our analysis was limited to LAD infarctions. Additional studies are needed to extend our findings to infarctions in other coronary territories.
Conclusion

Native T1 mapping at 3T can reliably determine infarct location, size, and transmurality of CMI with high diagnostic accuracy that is comparable to conventional LGE imaging. Given its non-reliance on exogenous contrast media, potential efficiency improvements associated with workflow during imaging sessions, and quantitative nature, native T1 mapping provides an appealing alternative for viability imaging when LGE imaging is contraindicated. Patient studies are necessary for clinical translation.

Figure Legends

**Figure 1. Detecting acute myocardial infarction at 3T.** Representative LGE images and T₁ maps of basal, mid-ventricular and apical slices acquired at 7 days post MI from a canine scanned at 3T are shown. Infarcted myocardium (highlighted blue pixels in the processed images) was identified on both LGE images and T₁ maps using the mean+5SD criterion with respect to the reference ROI drawn in remote myocardium (blue contour). Bulls-eye plots depicting the extent and transmurality of the infarcted myocardium are also shown for both LGE images and T₁ maps. The number within each segment indicates the percentage volume of that segment that was detected as infarcted myocardium by the mean+5SD criterion. For transmurality, each slice was divided into 100 equally spaced chords with the first chord placed at the anterior insertion of the RV into the LV. Each concentric ring on the Bulls-eye plot represents each short-axis slice with the most basal slice represented by the outermost ring.

**Figure 2. Diagnostic performance of native T₁ maps for detecting acute myocardial infarction at 3T.** Bland-Altman analysis showed good agreement between LGE images and T₁ maps for measuring infarct size (A) and transmurality (B) in AMI at 3T. T₁ maps modestly overestimated infarct size and transmurality compared to LGE images. There were also strong correlations between LGE images and T₁ maps for measuring infarct size (R²=0.94, C) and transmurality (R²=0.72, D). ROC analysis showed that area under the curve was 0.96 (E) indicating a strong diagnostic performance of native T₁ maps for detecting AMI at 3T.

**Figure 3. Detecting chronic myocardial infarction at 3T.** Representative LGE images and T₁ maps of basal, mid-ventricular and apical slices acquired at 4 months post MI from a canine scanned at 3T are shown. Infarcted myocardium (highlighted dark blue pixels in the processed
images) was identified on both LGE images and T1 as in Figure 1. Hypointense core of chronic iron deposition within the hyperintense infarcted myocardium was not detected as infarcted myocardium by the mean+5SD criterion, and was manually included in the final analysis (highlighted light blue pixels in the processed images). Bulls-eye plots depicting the extent and transmurality of the infarcted myocardium are also shown for both LGE images and T1 maps. Excellent correlations were observed between LGE images and T1 maps in terms of the location, spatial extent and transmurality of the infarcted myocardium. Magnified views (on the right) of the infarcted myocardium detected on the mid-ventricular and apical slices clearly show the concordance between LGE images and T1 maps.

**Figure 4.** *Diagnostic performance of native T1 maps for detecting chronic myocardial infarction at 3T.* Bland-Altman analysis showed excellent agreement between LGE images and T1 maps for measuring infarct size (A) and transmurality (B) during the chronic phase at 3T. Excellent correlations were observed between LGE images and T1 maps for measuring infarct size ($R^2=0.97$; C) and transmurality ($R^2=0.75$; D). ROC analysis showed that the area under the curve was 0.99 (E).

**Figure 5.** *Diagnostic performance of native T1 maps for detecting acute myocardial infarction at 1.5T.* Bland-Altman analysis showed moderate agreement between LGE images and T1 maps for measuring infarct size (A) and transmurality (B) using the mean + 5SD criterion at 1.5T in AMI. T1 maps significantly underestimated infarct size and transmurality compared to LGE images. However, strong correlations were observed between LGE images and T1 maps for measuring acute infarct size ($R^2=0.86$; C) and transmurality ($R^2=0.77$; D). ROC analysis showed that area under the curve was 0.86 (E).
Figure 6. Diagnostic performance of native $T_1$ maps for detecting chronic myocardial infarction at 1.5T. Bland-Altman analysis showed poor agreement between LGE images and $T_1$ maps for measuring infarct size (A) and transmurality (B) during the chronic phase at 1.5T. $T_1$ maps greatly underestimated infarct size and transmurality compared to LGE images. Moderate correlations were observed between LGE images and $T_1$ maps for measuring infarct size ($R^2=0.44$; C) and transmurality ($R^2=0.51$; D). ROC analysis showed that area under the curve was 0.79 (E).

Figure 7. $T_1$ and $T_2$ characteristics of infarcted myocardium at 1.5T and 3T during acute and chronic phases of infarction. Representative LGE images, $T_1$ maps and $T_2$ maps acquired at 1.5T and 3T from four different canines at 7 days and 4 months post MI are shown. Arrows point to the hyperintense sites of LGE, $T_1$ and $T_2$. Significant $T_1$ and $T_2$ increases were visually evident within the infarcted territories in AMI at 3T. While $T_1$ elevations persisted at 4 months post MI at 3T, $T_2$ of the infarcted myocardium returned to baseline levels. At 1.5T, $T_1$ and $T_2$ of infarcted myocardium were not visually different from those of remote myocardium in CMI at 1.5T.

Figure 8. Histopathological validation of replacement fibrosis detected on LGE images and native $T_1$ maps during the chronic phase of MI at 3T. Representative LGE images and $T_1$ maps acquired from three different canines scanned at 3T at 4 months post MI are shown along with the corresponding ex-vivo slice-matched TTC and EMT-stained images. Highlighted blue pixels on the processed images show the site of infarction on LGE images and $T_1$ maps, while arrows point to the site of infarction in TTC and EMT images. Both LGE images and $T_1$ maps agreed well with ex-vivo TTC images in terms of spatial location of the infarcted myocardium. $T_1$ maps...
could reliably detect infarctions ranging in size from 1.2% of the total LV (Dog 1) to 12.9% of the total LV (Dog 3). Highlighted light blue pixels on the processed T1 map from dog 3 point to the presence of chronic iron deposition. Corresponding to the chronic iron deposition seen on T1 map, TTC image shows a yellow-brown discoloration in the necrotic core indicating the presence of iron. Additional histological validation using EMT staining confirmed extensive replacement fibrosis within the infarcted regions indicating that T1 hyperintensity in the chronic phase of infarction at 3T predominantly arose from fibrosis. Scale bars on the magnified views of EMT images measure 2 mm.

Supplementary Figure 1: Detecting acute myocardial infarction at 1.5T. Representative LGE images and T\textsubscript{1} maps of basal, mid-ventricular and apical slices acquired at 7 days post reperfusion from a canine scanned at 1.5T are shown. Infarcted myocardium was identified as in Figure 1. Good correlation was observed between LGE images and the T\textsubscript{1} maps in terms of location of the infarcted myocardium.
Supplementary Figure 2: Detecting chronic myocardial infarction at 1.5T. Representative LGE images and T₁ maps of basal, mid-ventricular and apical slices acquired at 4 months post reperfusion from a canine scanned at 1.5T are shown. The LGE image and T₁ map were poorly correlated with respect to the spatial extent and location of the infarcted myocardium. Note that in the apical slice, there is a complete mismatch in the infarcted myocardium detected by the LGE image and the T₁ map. T₁ hyperintensity
observed in the apical slice was possibly due to partial volume effects. Bulls-eye plots showed significant underestimation of infarct size and transmurality on T₁ maps relative to LGE images (p<0.001 for both cases).
